ABSTRACT

Objectives To identify potentially modifiable factors that mediate the association between symptomatic osteoarthritis (OA) and premature mortality.

Methods A population-based prospective cohort study; primary care medical record data were linked to self-report information collected by questionnaire in adults aged 50 years and over (n=10 415). OA was defined by primary care consultation and moderate-to-severe pain interference in daily life. A Cox proportional hazards analysis determined the total effect (TE) of OA on mortality after adjustment for potential confounders. Within the Cox model, path analysis was used to decompose the TE to assess the indirect and direct effects for selected potential mediators (anxiety, depression, unrefreshed sleep and walking frequency). Results are expressed as HRs with 95% CIs derived from bootstrap resampling.

Results OA was significantly associated with mortality (TE-adjusted HR 1.14; 95% CI 1.00 to 1.29). The indirect effects for walking frequency were 1.05 (95% CI 1.04 to 1.06), depression 1.02 (95% CI 1.02 to 1.03), anxiety 1.01 (95% CI 1.00 to 1.02) and unrefreshed sleep 1.01 (95% CI 1.00 to 1.01).

Conclusions The analysis indicates that encouraging people to walk and 'get out and about' in addition to targeting OA could be protective against excessive mortality. The findings also suggest that depression, anxiety and unrefreshed sleep have a role in premature mortality for people with OA; however, this has low clinical significance.

Key messages

What is already known about this subject?
► Osteoarthritis (OA) is a serious disease; however, its relationship with mortality is unclear due to heterogeneity between studies and differences in approaches to the inclusion of covariates.
► While studies have adjusted for potential confounding and used regression modelling to highlight important covariates, they have not clearly identified the mechanisms that increase the risk of mortality in people with OA, which will inform future management and preventative strategies.

What does this study add?
► The study uses a technique for mediation within a survival model to identify the pathways and modifiable targets to reduce mortality in people with OA.

How might this impact on clinical practice?
► It highlights the need to focus on the impact, in addition to the condition itself, to reduce mortality in the large and growing number of people with OA.
► Focusing on encouraging people to walk frequently or 'get out and about' is important for reducing mortality in people with OA; while depression, anxiety and unrefreshed sleep appear to have a role, the clinical significance is low.

INTRODUCTION

There is increasing interest in mortality as an outcome of osteoarthritis (OA) due to the sheer frequency and expected increase in the prevalence of the condition, and significant association with comorbidities, such as cardiovascular disease (CVD).[1–3] Meta-analysis of studies examining the relationship between OA and mortality have highlighted conflicting results; however, this is due to differences in case and mortality definitions, selection of confounders and selection bias.[4–6]

More recent reviews highlight a positive association between lower limb OA and cardiovascular mortality[1 7]; there have been reports of positive associations between radiographic knee OA and cause-specific mortality (CVD, diabetes and renal disease),[8] symptomatic knee pain and cardiovascular mortality,[9] and doctor-diagnosed OA with mortality linked to heart failure.[10] Walking disability has been linked to the increased link between lower limb OA and mortality.[4 11 12]

Understanding links between OA and all-cause mortality remains important to allow comparisons with other health conditions. Recent studies in the USA have highlighted

Figure 1 Proposed pathways between osteoarthritis and mortality; direct and indirect effects through low walking frequency, depression, anxiety and unrefreshed sleep. BMI, body mass index.

a positive association between symptomatic lower limb OA and all-cause mortality.[7] While studies have adjusted for potential confounding and used regression modelling to highlight important covariates, the mechanisms that increase the risk of all-cause mortality in people with OA, which will inform future management and preventative strategies, are under-researched.[1 3–12] It is unclear whether the increased risk is due to the OA itself or to its impact which forms pathways to premature mortality. This paper builds on previous work to examine potential pathways that explain the link between OA and all-cause mortality with the aim of identifying modifiable targets.[13–15] Physical disability, which often follows lower limb OA,[13 14] has been identified as one mechanism that explains the increased risk of mortality, and is a target for healthcare.[15] Infrequent walking and physical activity, which is associated with physical disability and premature mortality,[16] may be a target that is relevant to all with OA (not only those with physical disability) and be part of self-management, optimal primary care and prevention of other comorbidities that may increase mortality risk, such as CVD and diabetes.[17] The analysis also explores the role of mood (anxiety and depression) and unrefreshed sleep; it is possible that OA increases anxiety, depression and unrefreshed sleep which leads to premature mortality (figure 1).[18–21] Mediation analysis is used to investigate pathways, although this has rarely been undertaken using survival analysis due to the challenge of accounting for time. The aim of this study was to examine potential mechanisms of the impact of OA on all-cause mortality, based on a novel technique for mediation analysis within a survival model. Specifically, the study tests the hypotheses that premature mortality is associated with symptomatic OA and is mediated through walking frequency, depression, anxiety and unrefreshed sleep.

METHODS
Design, study setting and population
The North Staffordshire Osteoarthritis Project (NorStOP) is a population-based prospective cohort study.[22] The sampling frame comprised individuals aged 50 years and over who were registered to receive care from one of six general practices in North Staffordshire, UK, gave written consent for medical record review and were mailed a baseline questionnaire, between April 2002 and May 2003, which collected data on health and socio-demographic factors. In the UK, general practice registers offer a convenient sampling frame for population-based studies; an estimated 98% of the UK residents are registered. Reminders were sent to non-responders 2 and 4 weeks after the initial mailing.

Of 10 432 potential participants who gave consent to medical record review, OA status could be determined for all; however, 17 (0.16%) had missing data on vital status (figure 2); this figure was deemed negligible and these 17 participants were removed from the analysis. Of the remaining 10 415 participants, 2233 (21.4%) did not have complete data on mediators and confounders; participants with incomplete data were on average significantly older and more likely to be female. To obtain data for the primary analyses, multiple imputation by chained equations was used to impute missing data[23] in Stata V.13. All confounders, mediators and outcome were used in the multiple imputation model; logit regression models were specified for binary variables and one skewed continuous variable (cognitive behaviour) was normalised prior to imputation, and transformed back to its original scale afterwards. The two-stage calculation was used to determine the number of required imputations, which was 32.[24]

Identification of OA
A combination of medical record and questionnaire data was used to identify symptomatic OA.[25] General practitioners in the study used the hierarchical Read code system to code the reasons for clinical encounters in primary care consultations.[26] Morbidity data (ie, symptoms and diseases) in this system are grouped under 19 main Read chapters. Data collected at the second hierarchical level or above were used to identify diagnostic groups. Individuals were defined as having OA if they had consulted general practice for OA between 2000 and 2008 based on Read code N05., and indicated moderate-to-severe pain interference on daily life in the Medical Outcomes Short Form 36 at baseline.[27] As OA is a long-standing, often progressive chronic condition, it was assumed that a clinician-established diagnosis at any point during the study period implied that OA was likely present at least to some degree during the entire period of observation.
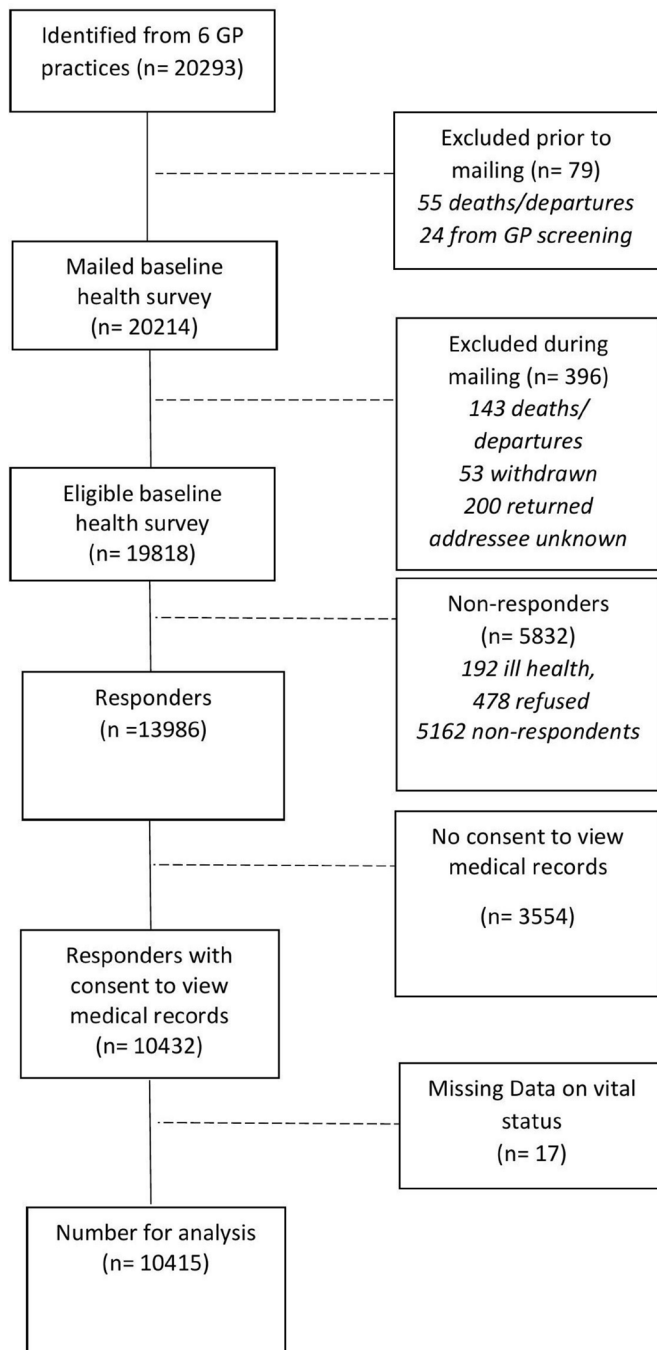

Figure 2 Flow of study participants. GP, general practitioner.

Outcome

Vital status was obtained from the patient registration system held at the local primary care trust and from dates notified to the NorStOP project team. These later dates of death were confirmed using manual tracing of the National Health Service Summary Care Record Demographic system. The outcome of interest was time to death, and was taken as time from the date of baseline questionnaire completion to the date of death or censoring took place. Information on vital status was available until 01 October 2012 and this is the censor date for those who survived.

Proposed mediators

The technique to perform mediation analysis required all mediators to be binary.[28–30] Depression and anxiety were measured using the Hospital Anxiety and Depression Scale. Raw scores were categorised as no depression/anxiety (0–7) or depression/anxiety (possible/probable cases; 8–21).[31] Walking frequency was measured using a single item ('Thinking about the past 4 weeks, how often do you go out for a walk? All/most/some/few/no days'). Using the median value, participants indicating all/most/some days were considered as frequent walkers (high frequency) and few/no days were considered as infrequent walkers (low frequency).[22] One item from the Estimation of Sleep Problems Scale was used to identify unrefreshed sleep.[32] Participants indicating that they experienced difficulties in the non-restorative sleep item ('During the past 4 weeks, did you wake up after your usual amount of sleep feeling tired and worn out?') on most nights in the past 4 weeks were classified as having unrefreshed sleep and compared with those who experienced no difficulties on some nights.[33]

Confounders

Comorbidities, sociodemographic and lifestyle factors associated with OA and morbidity were included as confounders.[1 3–14] Medical records were used to identify ischaemic heart disease, chronic obstructive pulmonary disease and diabetes in the same manner as for OA (ie, primary care consultation between 2000 and 2008). Number of prescriptions for non-steroidal anti-inflammatory drugs were also captured during the same period, dichotomised at zero, which was the median number of prescriptions. To cover all CVD, we included self-reported measures and asked responders to indicate if they had 'heart problems' or 'raised blood pressure'. Age, gender, educational attainment, occupational socioeconomic status, smoking status and cognitive impairment were all reported by questionnaire. Educational attainment (finished education on leaving school; gone onto full-time education including college or university) was included as a proxy measure of lifetime socioeconomic status. Participants' current or most recent job was categorised to non-manual or manual.[34] Self-report of current smoking status was categorised to current versus non-smoker. Cognitive impairment was measured using the cognitive and alertness behaviour subscale of the Functional Limitations Profile; scores range from 0 to 100.[35] Body mass index (BMI) was calculated from participants reported height and weight.

Statistical analysis

Cox proportional hazard modelling was used to obtain associations between OA and time to death, presented as HRs with 95% CIs. First, unadjusted associations were obtained, followed by adjustment for all confounders. The proportionality of the hazards assumption was assessed via likelihood-ratio test comparing a model including time-dependent constructs of all confounders to a smaller model including time-fixed constructs only.

Censoring was assumed non-informative and was taken as the earliest of withdrawal from the study/departure from practice or 01 October 2012.

The technique to perform mediation analysis within survival analysis was based on a counterfactual framework.[28 29] Within the counterfactual framework, each participant is observed under one set of circumstances and then consideration is given to what would have happened under counterfactual circumstances. This involves replication of analyses, where in the first instance, the exposure takes the original value and in the replication, it takes the opposite or counterfactual value. Weights are derived from logistic regression of the binary mediator on the exposure and confounders.[29] When the assumptions of proportional hazards and non-informative censoring are met, the weighted Cox regression model will give HRs which are estimates of the indirect and direct effects; the indirect effect is the 'amount' of mediation and the extent to which each proposed mediator explains the link between OA and mortality, while the direct effect is the extent of the remaining link between OA and mortality once the indirect effect of the proposed mediator is accounted for. The product of these two HRs provides the HR for the total effect (TE) (ie, the overall association between OA and mortality). CIs were calculated using bootstrapping to account for the non-normal distribution of the.[29] This analysis was performed using code developed for the statistical package R.[29 30]

First, associations between OA and each mediating variable were examined using logistic regression; all associations between OA and potential mediators were adjusted for potential confounders and are presented as ORs with 95% CIs. Results of the mediation analyses (carried out using the described technique) are presented as HRs for the direct, indirect and total effects with associated bootstrapped 95% CIs. Mediation was indicated by the presence of a significant indirect effect. The descriptive analysis was performed using Stata V.13 and the survival and mediation analyses were carried out using R.

Sensitivity analyses
Sensitivity of the findings from the primary analyses was assessed when only those participants with complete mediator and confounder data were used (n=8182). Sensitivity analysis was performed to assess the robustness of findings to potential unmeasured confounding, using the E value approach introduced by VanderWeele and Ding[36]; E value represents the minimal needed association between a confounder and both the outcome and exposure to fully explain observed associations.

RESULTS
Cohort characteristics
Of the 10 415 participants, 3172 (30.5%) of the sample had OA (table 1). The mean age was 66.2 years (SD 10.2 years) and 53.8% were female. The median time from the date of questionnaire return to death among those

who died (1643 (15.8%)) was 2076 days (range 1–3807). Table 1 also gives detail on completeness for each of the patient characteristics.

Relationship between OA and mortality
Of those with OA, 606 (19.0%) died during the study period, compared with 1039 (14.3%) who didn't have OA; median person-time (IQR) of follow-up was 3674 days (3461–3835) cf. 3646 days (3472–3834). Figure 3 shows survival function plots over 10 years for those with and without OA. Incidence mortality rate per 1000 person-years was 1.06 among those with OA and 1.04 among those without, with unadjusted HR 1.30 (95% CI 1.22 to 2.30). The association between OA and time to death was attenuated when adjusted for confounders; adjusted HR was 1.11 (95% CI 1.06 to 1.17). E value associated with the estimate was 1.36 (and 1.25 for the lower CI); this is the association that an unmeasured confounder would have to have with both OA and mortality, conditional on measured confounders, to fully explain the observed association. The likelihood-ratio test did not reveal a significant difference between models with and without time-dependent constructs of confounders (χ^2=11.79, p value=0.1078); it is plausible to assume that proportionality of hazards assumption was satisfied.

Mediation of association between OA and mortality
OA was positively associated with all of the proposed mediators (table 2). Corresponding E values are also given in table 2. The adjusted indirect effects for low walking frequency were 1.05 (95% CI 1.04 to 1.06), depression 1.02 (95% CI 1.02 to 1.03), unrefreshed sleep 1.01 (95% CI 1.00 to 1.01) and anxiety 1.01 (95% CI 1.00 to 1.02). Notable attenuation in the direct effects occurred when walking frequency was included as a mediator (1.05 (95% CI 1.00 to 1.10)). Direct effects for depression, anxiety and unrefreshed sleep were 1.08 (95% CI 1.03 to 1.13), 1.10 (95% CI 1.05 to 1.015) and 1.09 (95% CI 1.05 to 1.14), respectively.

When analyses were restricted to only those with complete mediator and confounder data (n=8182), the findings were generally similar; however, analyses based on imputed data gave estimates which were closer to the null, and more precise (table 3).

DISCUSSION
This study examined potential mechanisms between OA and all-cause mortality within a survival model with the aim of identifying potentially modifiable targets for healthcare.[29] The findings indicate a positive association between symptomatic OA and all-cause mortality and highlight frequent walking as a potential target to reduce all-cause mortality. While anxiety, depression and unrefreshed sleep had statistically significant effects, the extent of their mediation effect has low clinical significance.

While the HRs in the analysis can be considered to be low (adjusted HR 1.11 (95% CI 1.06 to 1.17) following

adjustment for other key confounders, the increased link of mortality is applicable to a large number of people in the general population who have symptomatic OA. Walking frequency explained the greatest amount of the link between OA and premature mortality (indirect effect 1.05 (95% CI 1.04 to 1.06) cf. TE 1.10 (95% CI 1.05 to 1.15)). The extent of the indirect effect was comparable to that for physical function, measured via speed of walking, on the link between radiographic hip OA and

CVD mortality. This finding also links with previous work which has indicated that walking disability is associated with premature mortality in older adults with OA,[7 8 11 15] as walking disability leads to reduced walking frequency.[3] However, of the low-frequency walkers with OA, more than one in five (22.7%), one in three (34.6%) and two of three (65.0%) had little or no limitation walking more than one mile, half a mile or 100 yards, respectively, indicating that limitation is not always the barrier to frequent walking. Encouraging people to maintain levels of walking and physical activity and targeting a reduction in physical limitation in clinical practice to allow this is important. Low walking frequency is linked with a number of anatomical (eg, muscle weakness) and physiological impairments (eg, hypercholesterolaemia and hypertension) which leads to comorbidity, such as CVD and diabetes, which are associated with premature mortality.[37] Small amounts of regular walking and getting out and about can offer protection against comorbidity, including depression and CVD.[38]

While the indirect effects of depression, anxiety and unrefreshed sleep can be considered as statistically significant, the level of clinical significance is debatable. In this analysis, 18.2%, 9.1% and 8.3% of the increased risk of all-cause mortality in people with OA were explained by depression, anxiety and unrefreshed sleep, respectively; although the adjusted association between OA and

Table 2 Pathways between osteoarthritis and mortality via walking frequency, depression, anxiety and unrefreshed sleep: total, direct and indirect effects

all-cause mortality is also low (ie, HR 1.14). The role of depression, anxiety and unrefreshed sleep on mortality is often unclear due to confounding from comorbidity and sociodemographic and lifestyle factors,[39] although in these analyses, all three continued to explain, even if small, a role in people with OA. While links with physical function may explain part of the mechanism for unrefreshed sleep, anxiety and depression, further research is required to further clarify these pathways. The selection of confounders in studies of OA and mortality prompts debate over the role of covariates. Obesity was included in this study as a confounder, while in other studies, it has been highlighted as having a role in mortality for people with knee OA.[1 7 8] In additional analysis, in this study, obesity exerted no significant mediating effect on the pathway between OA and mortality (indirect effect 1.00 (95% CI 0.98 to 1.01)).

The study has a number of strengths. A clinical definition of OA, which captured the presence of symptomatic OA, was used and mortality data were obtained from a national data source.[25] The diagnoses of OA in medical records was dependent on clinicians' approaches to identifying OA and is based on a range of factors linked to the clinical syndrome and may include radiographic signs; this may lead to misclassification of OA. High rates of sensitivity (82%[40]) and specificity (100%[41]) have been reported for OA identified via medical records but these estimates are dependent on the reference standard selected. The diagnoses of OA in medical record may also underestimate the diagnoses of hand OA and it is expected that there will only be a small number of people classified as having OA who have only hand OA[42];

the majority of those with OA in this study will have lower limb OA.

This study was a large, population-based study sampled from the general population. The response rate was high and was comparable to other population-based studies that have used postal questionnaires. The available data covered important mediators and confounders of the relationship between OA and mortality.[1 3–15] Limitations of the data were that joint-specific OA was not coded in the electronic health record data and cause-specific mortality could not be identified; this prevented analysis of the relationship with mortality with lower limb OA and a focus on CVD which has been identified as the cause of mortality most pertinent for OA.[7 8] Self-reported data was included; while this self-report data can be limited by inaccuracies, through recall bias or misinterpretation of questions, it is the most appropriate method to collect data on the impact of OA. Validated questionnaires were used to capture these constructs.[22 27 32] To adjust for potential misclassification of BMI due to discrepancies in self-reported height and weight, the analysis was adjusted for sociodemographic factors, including age, gender, education and occupational status, resulting in a close approximation of actual BMI.[43 44] The severity of OA could not be identified in this data and maybe a confounder of the relationship between OA and mortality and impact on the estimates of the indirect and direct effects when mediators were examined. In addition, there may be other confounders that are significant but were not included in this study. Sensitivity analysis indicated that unmeasured confounders would need to have a moderate association with OA and mortality in addition to the factors

already included to impact on the estimates. The need for binary variables for this analysis may result in the loss of precision and misclassification.[45][46] This also prevented examination for trends in the extent of mediation with increasing levels of exposures.[46]

The study is longitudinal in nature; however, OA and the mediating and confounding factors were measured at the same time point. While modelling the relationship and pathways between OA and mortality is challenging, the method used in this analysis is currently the best approach to understanding the complex relationship.[47] Although the causal inferences indicated by this analysis should be interpreted with caution, the findings provide empirical support for the proposed theoretical mechanism and targets for interventions.[29][47] The analytical method used is limited to including one binary mediator at a time. This may underestimate the effect of potential mediators and also prevents further exploration of the complex relationship, for example, identifying reasons for the mediating effect of depression and unrefreshed sleep, and the further role of comorbidity. Consideration of multiple hypotheses simultaneously increased the likelihood of a type 1 error[48] and it was not possible to correct for this here.

This study suggests that further research on understanding the link with mortality should focus on clinical/symptomatic OA. The potential to examine for mediation and test pathways within Cox proportional models indicate a need to move away from adjusted regression models to identify targets for interventions to reduce mortality linked to OA. Further development of statistical models is required to further understand the complex relationship between OA and mortality.

In conclusion, the findings of the study indicate the significant relationship between symptomatic OA and mortality. The common occurrence of OA in the general population indicate clinical and population approaches to reduce the impact and reduce mortality. This approach to understanding the pathway from OA to mortality indicates that walking frequency is a key target to reduce mortality; small amounts of frequent walking and getting out and about could reduce the extent of premature mortality in people with OA. The mediating effect of depression, anxiety and unrefreshed sleep was of low clinical significance.
