Bleeding After Hospital Discharge Following Acute Coronary Syndrome: Incidence, Types, Timing, and Predictors

Nafiu Ismail, MPH; Kelvin P. Jordan, PhD; Umesh T. Kadam, PhD; John J. Edwards, PhD; Tim Kinnaird, MD; Mamas A. Mamas, PhD

***Background*—**The incidence and predictors of bleeding after acute coronary syndrome are unclear within the real-world setting. Our objective was to determine the incidence, types, timing, and predictors of bleeding complications following hospital discharge after acute coronary syndrome.

***Methods and Results*—**We used the Clinical Practice Research Datalink, with linkage to Hospital Episode Statistics, to determine the incidence, timing, and types of bleeding events within 12 months after hospital discharge for acute coronary syndrome. We assessed independent associations between postdischarge bleeding and baseline patient characteristics using a competing risk regression model, accounting for death as a competing event. Among 27 660 patients surviving to hospital discharge, 3620 (13%) experienced bleeding complications at a median time of 123 days (interquartile range, 45–223 days) after discharge. The incidence of bleeding was 162/1000 person-years (95% CI, 157–167/1000 person-years) within the first 12 months after hospital discharge. Bruising (949 bleeds [26%]) was the most common type of first bleeding event, followed by gastrointestinal bleed (705 bleeds [20%]), whereas intracranial bleed was relatively rare (81 bleeds [2%]). Significant predictors of postdischarge bleeding included history of bleeding complication, oral anticoagulant prescription, history of peripheral vascular disease, chronic obstructive pulmonary disease, and advanced age (>80 years). Predictors for postdischarge bleeding varied, depending on the anatomic site of the bleeding event.

***Conclusions*—**Bleeding complications after hospital discharge for acute coronary syndrome are common. Patients who experience these bleeding events have distinct baseline characteristics, which vary by anatomic site of the bleed. These characteristics can inform risk-benefit considerations in deciding on favorable combination and duration of secondary antithrombotic therapy. **(*J Am Heart Assoc*. 2019;8:e013679. DOI: 10.1161/JAHA.119.013679.)**

Key Words: hemorrhage • incidence • postdischarge • real world • risk factors • sites

The management of acute coronary syndrome (ACS) with antithrombotic medications achieves the desired goal of reducing the risk of future ischemic events. But these reductions are accompanied by bleeding complications.[1]

In clinical trials, the incidence of major bleeding complications is reported to be between 1% and 10%, depending on the bleeding definition used,[2–4] with observational studies reporting incidences of between 2.8%[5] and 11%.[6] However, the emphasis in most of these studies has been on major in-hospital or 30-day bleeding events (a composite of in-hospital and postdischarge events), with little consideration for events in the longer term after hospital discharge. After hospital discharge, patients with ACS often remain on dual antiplatelet therapy for up to a year, and aspirin indefinitely, so their risk of bleeding complications persists in the longer term.[7]

Major in-hospital bleeding has been associated with sociodemographic characteristics, cardiovascular and noncardiovascular comorbidities, and pharmacological and procedural characteristics,[8–10] leading to the development of risk scoring algorithms that stratify patients into risk profiles for these bleeding events.[8–10] However, it is unclear whether these characteristics are also predictive of bleeding events after hospital discharge. For example, procedural characteristics may become less relevant in predicting the risk of postdischarge bleeding events, whereas patient

Clinical Perspective

What Is New?

- Bleeds after hospital discharge for acute coronary syndrome are common, with bruising and gastrointestinal bleeds the most common.
- History of bleeding complications, chronic obstructive pulmonary disease, peripheral vascular disease, management with oral anticoagulants after hospital discharge, and aged >80 years were the most significant determinants of postdischarge bleeding.
- Predictors for postdischarge bleeding varied, depending on the anatomic site of the bleeding event.

What Are the Clinical Implications?

- These baseline predictors can assist clinicians in identifying patients at risk of bleeding complications after hospital discharge so that longer-term antithrombotic therapy can be tailored to fit an individual patient's risk profile.

characteristics and pharmacological choice may become more important after discharge. The few studies that have reported on characteristics associated with postdischarge bleeding events have mostly been randomized controlled trials,[11–13] where minor bleeding events, high-risk multimorbid "real-world" patients, and those receiving long-term oral anticoagulation (a potential risk factor for bleeding) have been excluded. Therefore, the generalizability of these studies to the wider population with ACS in the real-world setting is unclear.

While the nature of in-hospital bleeds and their predictors have been well described,[8–10,14] the incidence, types, and predictors of bleeding events that occur after hospital discharge are unclear. The first objective of this study was to determine the incidence, timing, and types of bleeding events within 12 months after hospital discharge. The second objective was to determine the predictors of bleeding events and site-specific bleeds after hospital discharge.

Methods

The data, analytic methods, and study materials will not be made available to other researchers for purposes of reproducing the results or replicating the procedure.

Study Design and Setting

This was a cohort study set within the Clinical Practice Research Datalink (CPRD),[15] with linkage to Hospital Episode Statistics (HES) and Office for National Statistics mortality data. CPRD is a primary care electronic healthcare record database containing anonymized routinely collected consultation records from >670 general practices in the United Kingdom. The CPRD population is representative of the UK population on age, sex, and ethnicity.[15] Practices included in our analysis (n=377, all from England) had to have linked HES and Office for National Statistics mortality data. Practices with and without such linkage are similar in respect of demographic data, years of follow-up, and prescribing.[16] The CPRD data set is described further in Data S1. HES is a secondary care database containing detailed information on diagnosis, procedures, admissions, and discharge dates from National Health Service hospitals or hospitals where the cost of care is reimbursed by the National Health Service. The National Health Service is the main healthcare provider in the United Kingdom that is free at the point of care. The Office for National Statistics mortality data contain records of date of death and the underlying cause of death of all deceased individuals in the United Kingdom. The validity of diagnoses for conditions such as ACS is high in both CPRD and HES.[17,18] The study was approved by the CPRD Independent Scientific Advisory Committee (protocol No. 17_181). The requirement for informed consent was waived because these databases are anonymized following strict confidentiality guidelines before being distributed for research purposes.

Study Population

Patients were included in the study if they were aged ≥18 years, with a primary care record for ACS in CPRD between 2006 and 2016 and a matching ACS record in HES within 1 month of the primary care ACS event, but without a primary care record of ACS in the preceding 2 years. The period of 2 years was selected to identify only incident ACS cases. The index date for each patient was the date of hospital discharge after the matched ACS event in HES. Read codes and *International Classification of Diseases, Tenth Revision* (*ICD-10*) code lists used in defining ACS in CPRD and HES are available at http://www.keele.ac.uk/mrr. Patients were excluded if they did not survive to discharge, they had no discharge date recorded in HES, or their first ACS event preceded the date their registered practice was deemed to have up to standard data in CPRD.

Predictors

We identified potential predictors of bleeding by reviewing previously published risk scores for in-hospital and postdischarge bleeding events,[8–14,19–21] as well as studies that had reported on characteristics associated with bleeding after ACS.[22–26] Nineteen potential predictors were selected for inclusion in the study on the basis of clinical judgement.

These predictors included sociodemographic characteristics, cardiovascular and noncardiovascular comorbidities (recorded in the previous 2 years before the index date, except body mass index, which was defined as last measurement until 30 days after index date to capture the most recent body mass index for a patient), in-hospital procedures, and pharmacological characteristics (recorded in the previous 6 months before the index date in the case of NSAIDs and selective serotonin reuptake inhibitors, or within 90 days after hospital discharge in the case of antithrombotic drugs). See Table S1 for the full list of potential predictors and their baseline definitions.

Bleeding End Point

The outcome of bleeding was defined as having a diagnostic record for bleeding in a patient primary care record or a death record in Office for National Statistics mortality data, with bleeding as the underlying cause within 12 months after the index date. Bleeding events included gastrointestinal bleeding, hematemesis, melena, gastrointestinal ulcers with bleeding, intracranial bleeding, hemoptysis, epistaxis, hemarthrosis, hemopericardium, hematuria, vaginal bleeding, retinal bleeding, anemia caused by blood loss, spontaneous bruising, petechiae, spontaneous ecchymoses, and bleeding not elsewhere classified. Bleeding events were further classified based on site into bruising; respiratory/ears, nose, and throat; gastrointestinal; genitourinary; intraocular; and intracranial. Read codes used to define and classify bleeding events are available at http://www.keele.ac.uk/mrr. Where the date of the bleeding event was the same as the index date, these bleeding events were regarded as in-hospital bleeds and, therefore, excluded.

Follow-Up

For all analyses, patients who were discharged alive were longitudinally followed up for a maximum of 12 months for records of bleeding consultations after hospital discharge for ACS. Follow-up started from the index date (date of hospital discharge) until earliest of first bleeding event or date patient ceased contributing to CPRD because of death or transfer out of practice or practice leaving CPRD or the end of 12 months from the index date of hospital discharge or the date of last data collection at the time of data request.

Statistical Analysis

All analyses were based on a first bleeding event for a patient after hospital discharge for ACS. Baseline sociodemographic characteristics, comorbidities, in-hospital procedures, and pharmacological characteristics were descriptively compared between those who did and those who did not experience bleeding events within the first 12 months after hospital discharge. Continuous variables are presented as mean and SD or median and interquartile range, and they were compared using Student *t* test or Mann-Whitney test, as appropriate. Categorical variables are presented as frequencies and percentages, and they were compared using χ^2 test.

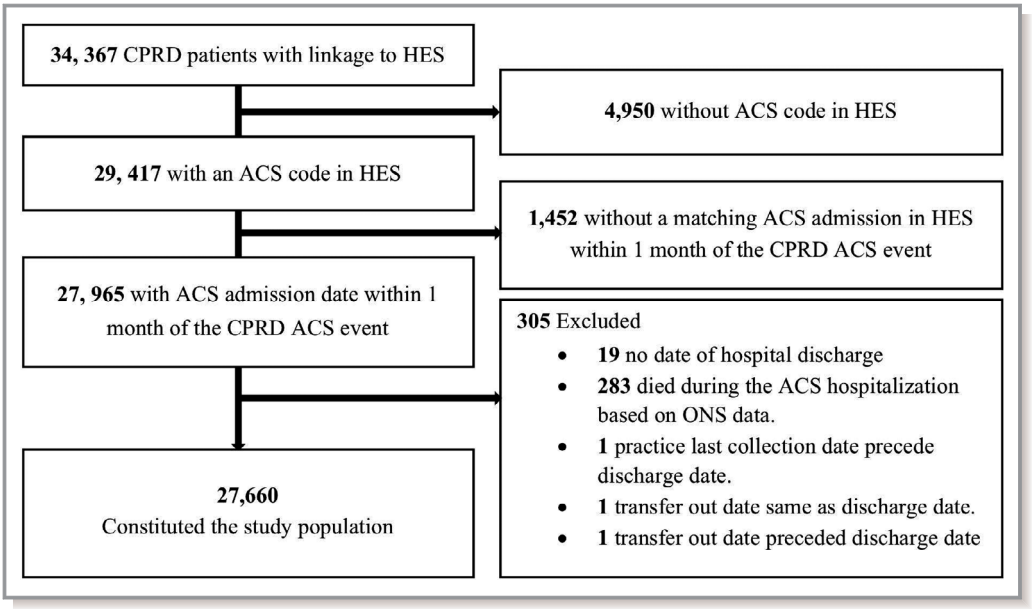

Figure 1. Flow diagram describing the steps involved in identifying the study population. ACS indicates acute coronary syndrome; CPRD, Clinical Practice Research Datalink; HES, Hospital Episode Statistics; ONS, Office for National Statistics mortality data.

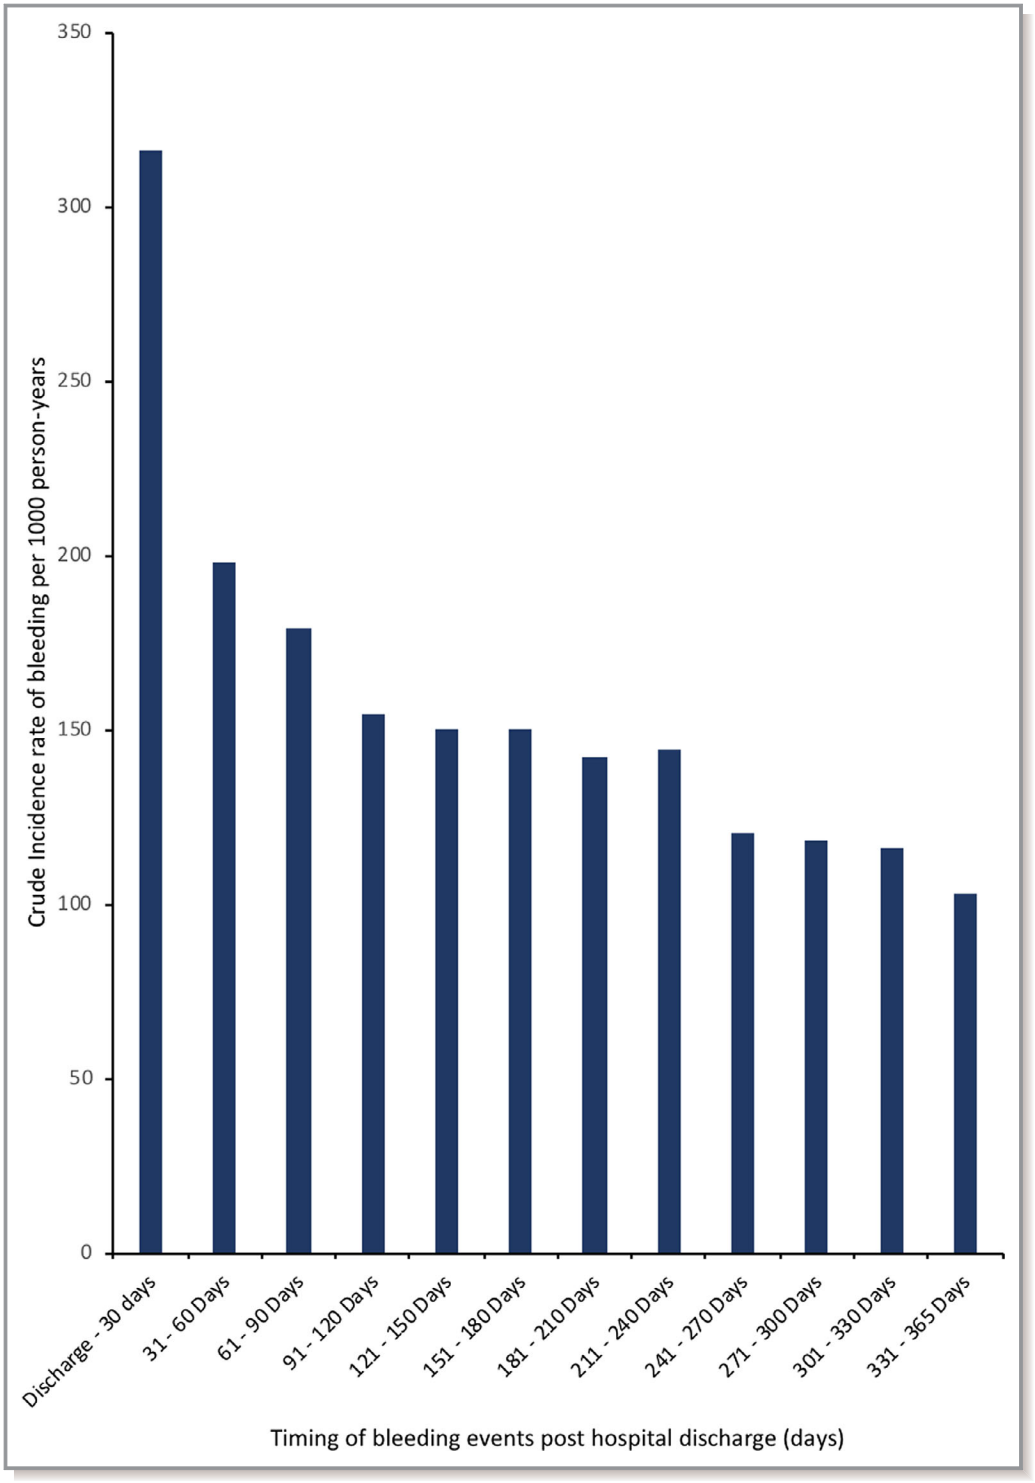

Figure 2. Crude incidence rates (per 1000 person-years) of bleeding within 12 months after hospital discharge by time from the date of hospital discharge.

Fine and Gray competing risk regression model[27] was used to determine univariable and multivariable associations between the outcomes of bleeding (and of each type of bleeding event) with potential predictors, accounting for death as a competing event, and reported using sub–hazard ratios (sHRs) with their corresponding 95% CIs. Death from a non-bleeding cause was selected as a competing event because of the older age of the cohort and will prevent a bleeding event occurring. All multivariable associations were adjusted for year of index hospital discharge, geographic region, and all

other potential predictors. Robust variance estimators were used to account for clustering within general practices. Fractional polynomials were used to determine the functional form of age, and a plot of age against rates of bleeding (per 1000 person-years) was then used to create cut points in categorizing age when the linear form was not appropriate. The proportional hazard assumption was examined by inclusion of time-by-covariate interactions in the final models.

To address missing data in smoking status and body mass index, multiple imputation (10 imputations) was performed.[28] To assess the impact of missing data, a sensitivity analysis was performed (for the outcome of all bleeds) in which only patients with complete data on all variables were included (complete case analysis). Results of the complete case analysis were compared with those from the imputed data analysis. Only results of analyses on the imputed data sets are presented here. Results of the complete case analysis are reported in Data S1. As a subgroup analysis, the predictors for bleeding in patients managed with percutaneous coronary intervention (PCI) during the ACS hospitalization were determined. All comparisons were 2 tailed, and $P<0.05$ was considered statistically significant. All analyses were performed using Stata, version 14.2.

Results

Incidence, Timing, and Types of Postdischarge Bleeding Events

Figure 1 shows the number of patients included in the study, with exclusions. A total of 27 660 patients constituted the study population, of which 3620 (13%) experienced 5041 bleeding events over a median follow-up of 365 days (interquartile range, 246–365 days) after hospital discharge. Of the 3620 patients with bleeding events, 947 (26%) had multiple bleeding events within the first 12 months of hospital discharge. Of those with multiple bleeding events, 69% (n=654) had 2 bleeding events, 21% (n=197) had 3 bleeding events, and 10% (n=96) had ≥4 bleeding events after hospital discharge. The median time to a first bleeding event within the first 12 months was 123 days (interquartile range, 45–223 days). The incidence of bleeding was 162/1000 person-years (95% CI, 157–167/1000 person-years), and bleeding events occurred more frequently in the first 30 days after hospital discharge (Figure 2).

Table 1 shows the incidence, timing, and types of bleeding events (based on first bleed). Bruising was the most common (26% of all first bleeds), followed by gastrointestinal bleeds (20%). The incidence was highest for bruising (42/1000 person-years) and lowest for intracranial bleeding events (3/1000 person-years).

Baseline Characteristics

Table 2 summarizes the baseline characteristics of those who experienced bleeding complications and those who did not within the first 12 months after hospital discharge for ACS. Patients who experienced bleeding complications after hospital discharge were, on average, older (mean, 72 versus 70 years) and more commonly ex-smokers with higher prevalence of baseline hypertension, chronic obstructive pulmonary disease (COPD), anemia, hyperlipidemia, chronic kidney disease, history of bleeding complications (in 2 years before the index date), and a lower level of hemoglobin. Those who experienced bleeding events were also more commonly treated with oral anticoagulants after discharge. The baseline characteristics of the study population, stratified by site-specific bleeding events, are summarized in Table S2. Patients who experienced bruising were, on average, younger (age, 70 years) and more commonly women, whereas those who experienced intracranial bleeds were mostly older (age, 76 years) with a higher prevalence of chronic kidney disease.

Predictors of Bleeding Events

Age violated the linearity assumption of the competing risk model and was, therefore, categorized. Predictors that violated the proportional hazard assumption were included in the relevant models as time-dependent coefficients. The change in risk of bleeding for each predictor that interacted with time, and was significantly associated with bleeding, is reported in Table S3 at 2 time points (at 30 and at 365 days) after hospital discharge.

The crude and adjusted associations of each predictor with bleeding are presented in Table S4. Figure 3 presents the

Table 1. Incidence and Timing of Each (First) Bleeding Event Within 12 Months After Hospital Discharge

Site of Bleed	Bleeding Events, No. (% of All First Bleeds)	Incidence Rate (per 1000 Person-Years) (95% CI)	Timing of Bleed Within 12 Months, Median (IQR), d

Number of patients with missing data: smoking (n=5188), BMI (n=8153), hemoglobin (n=8702), diastolic and systolic blood pressure (n=9592), white cell count (n=8914). ACS indicates acute coronary syndrome; BMI, body mass index; CKD, chronic kidney disease; COPD, chronic obstructive pulmonary disease; eGFR, estimated glomerular filtration rate; IQR, interquartile range; NSTEMI, non ST-segment–elevation myocardial infarction; PCI, percutaneous coronary intervention; PVD, peripheral vascular disease; SSRI, selective serotonin reuptake inhibitor; STEMI, ST-segment–elevation myocardial infarction; TIA, transient ischemic attack.

independent predictors for bleeding within the first 12 months after hospital discharge. After multivariable adjustment, age >65 years, female sex, history of hypertension, peripheral vascular disease (PVD), COPD, not having a history of heart failure, history of bleeding complications, management with PCI during the ACS hospitalization stay, use of NSAIDs, and treatment with oral anticoagulants or single antiplatelet after hospital discharge were independently associated with 12-month postdischarge bleeding events. The most significant predictors of bleeding were baseline history of bleeding complications (sHR, 1.88; 95% CI, 1.73–2.04), management with oral anticoagulants versus single antiplatelet after hospital discharge (sHR, 1.35; 95% CI, 1.17–1.55), aged >80 years versus aged ≤65 years (sHR, 1.42; 95% CI, 1.22–1.66), COPD (sHR, 1.29; 95% CI, 1.20–1.39), and PVD (sHR, 1.28; 95% CI, 1.09–1.50). The increased risk of bleeding in those managed with PCI or those aged >80 years (compared with those aged ≤65 years) was highest immediately after hospital discharge, but then decreased with time (Table S3).

Results of the sensitivity analysis did not reveal any disparities in findings between the imputed data analysis and the complete case analysis (Table S5). In the subgroup analysis, advanced age (>80 versus age ≤65 years), female sex, history of cancer, PVD, COPD, bleeding complications, and use of NSAIDs were the main predictors of bleeding events within the first 12 months after hospital discharge in patients managed with PCI (Figure 4). Treatment with oral anticoagulant was also associated with an increased risk of bleeding in patients managed with PCI, but this association did not reach statistical significance.

Predictors of Site-Specific Bleeding Events

Characteristics independently associated with each site-specific bleeding event are reported in Table 3. After multivariable adjustment, history of bleeding complications (sHR, 2.22; 95% CI, 1.87–2.64), advanced age (>80 versus ≤65 years) (sHR, 1.29; 95% CI, 1.01–1.65), and COPD (sHR, 1.29; 95% CI, 1.08–1.55) were the independent predictors of gastrointestinal bleeding events. Treatment with single antiplatelet after hospital discharge was also associated with an increased risk of gastrointestinal bleed. History of diabetes mellitus (sHR, 1.77; 95% CI, 1.08–2.89) and bleeding complications (sHR, 1.91; 95% CI, 1.05–3.45) were the main predictors of intracranial bleeds after hospital discharge. Treatment with oral anticoagulants, use of NSAIDs, history of PVD, aged 66 to 80 years, and advanced age (>80 years) were also associated with increased risk of intracranial bleed, but these associations did not reach statistical significance. Risk factors independently associated with each site-specific bleeding event are reported in Table 3.

Discussion

This is the first electronic health record–based study to examine the incidence, timing, and types of postdischarge bleeding events and their predictors from a primary care perspective. Our study reports that bleeding complications after hospital discharge are common and occur in ≈1 in 10 patients within the first 12 months after hospital discharge, with bruising and gastrointestinal bleeds the most common. We report that the median time to a first bleeding event was

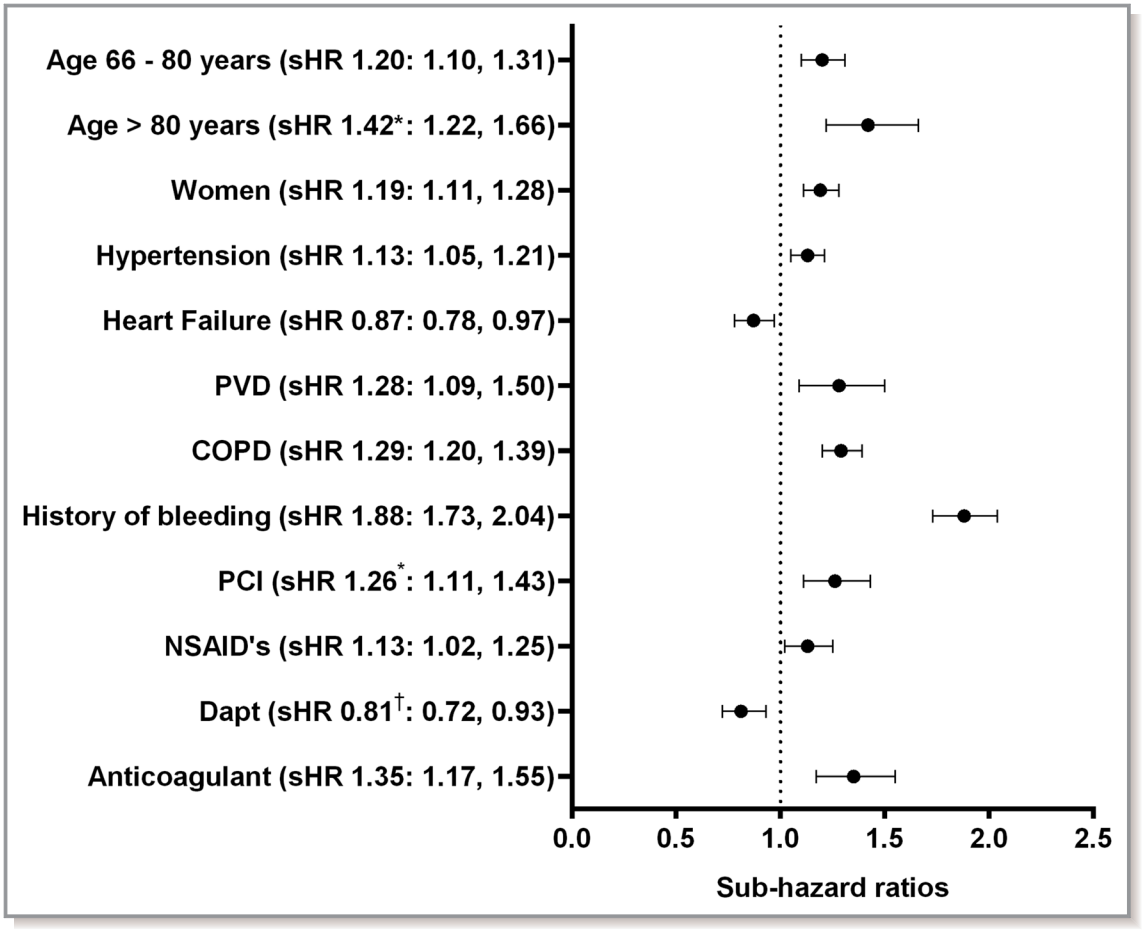

Figure 3. Characteristics associated with bleeding events within 12 months after hospital discharge for acute coronary syndrome. *Included as time-dependent coefficient: estimated sub–hazard ratio (sHR) at day of hospital discharge but decreases with time after discharge. †Included as time-dependent coefficient: estimated sHR at day of hospital discharge but increases with time after discharge. 123 days, with bleeding events more commonly occurring in the first 30 days after hospital discharge. Our analysis found that history of bleeding complications in 2 years before hospital discharge, management with oral anticoagulants after hospital discharge, COPD, PVD, and advanced age (>80 years) were the major predictors of bleeding complications in the first 12 months after hospital discharge. Predictors for postdischarge bleeding varied, depending on the anatomic site of the bleeding event. We report that characteristics, such as COPD, use of NSAIDs, and history of cancer, which have not been previously examined in a population with ACS, may carry greater risk for bleeding complications after hospital discharge.

The results of our study add granularity to the growing body of literature evaluating the risk of bleeding complications after hospital discharge. The finding that 13% of patients had experienced bleeding complications in the year after discharge was higher than those reported in the ADAPT-DES (Assessment of Dual Antiplatelet Therapy With Drug-Eluting Stents) study[29] and other previous studies in the postdischarge setting (range, 2.5%–7.9%).[30,31] This higher incidence likely reflects differences in the definition of bleeding used, as the emphasis in previous studies has been on major bleeding events. The higher incidence may also be because of the primary care population with elderly multimorbid patients, which were mostly excluded from randomized controlled trials. Our study did not capture bleeding events that are not actionable and did not cause patients to seek medical advice. This highlights that the actual incidence of postdischarge bleeding events may be higher than what we have reported. Our study and previous studies[25,26] have identified the first 30 days of hospital discharge as the period for greater vulnerability for these bleeding complications and highlight the time when resources can be better used to improve longer-term patient prognosis, such as by personalization of antithrombotic drugs at the time of hospital discharge. We

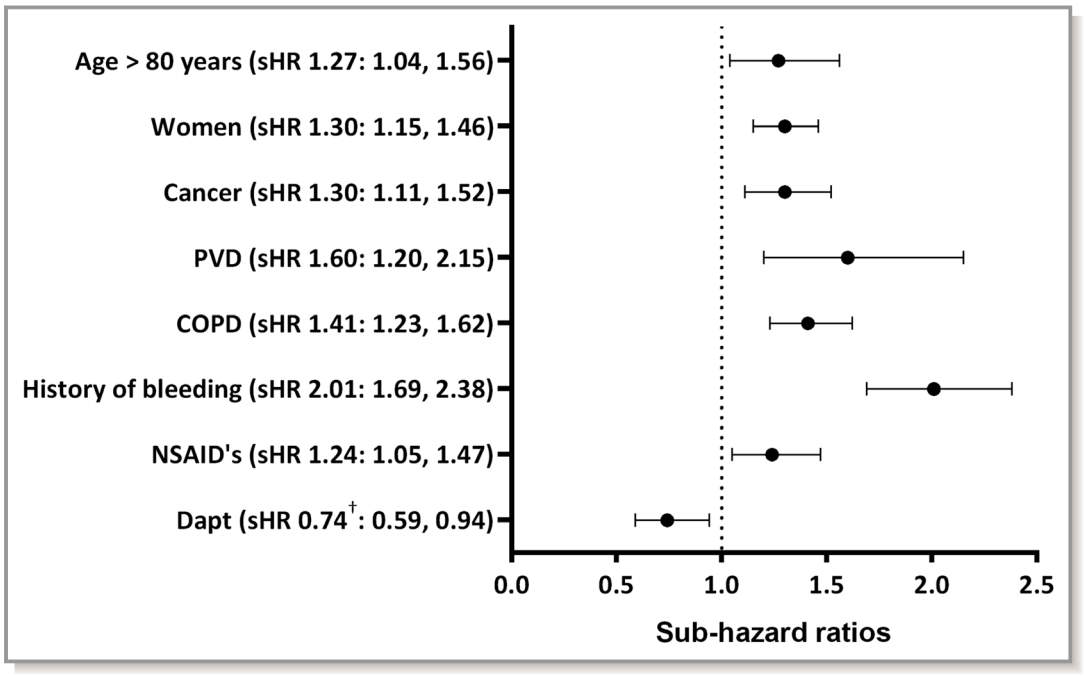

Figure 4. Characteristics associated with bleeding events within 12 months after hospital discharge for acute coronary syndrome in patients managed with percutaneous coronary intervention. †Included as time-dependent coefficient: estimated sub–hazard ratio (sHR) at day of hospital discharge but increases with time after discharge. report that bruising was the most common type of bleeding complication after hospital discharge. These types of bleeding events, which have mostly been neglected in previous studies, can be detrimental. Bruising may impact on patient quality of life, leading to discontinuation of antithrombotic therapy, which can have indirect adverse consequences.[32,33]

We found that the predictors (eg, age, hypertension, PVD, history of bleeding, management with PCI during ACS hospitalization, and use of oral anticoagulants)[8–10,14] for in-hospital bleeding have some overlap with those for postdischarge bleeding events. But characteristics, such as those related to ACS presentation, may carry less impact on risk of postdischarge bleeding. Although there was some overlap between the predictors for in-hospital and postdischarge bleeding events, the predictors for site-specific bleeds vary, depending on the anatomic site of the bleeding event.

A novel finding of this study in reviewing the predictors of site-specific bleeding complications was that, although characteristics such as advanced age (>80 years) and prior history of bleeding complications were predictive of all types of bleeding events (except bruising), some predictors were more associated with certain types of bleeds. We found that the female sex was only predictive of nuisance bruising, and not major bleeds (eg, gastrointestinal or intracranial bleeds), contrary to that reported by in-hospital studies.[8,9,14] This finding is consistent with most studies of bleeding in the postdischarge setting, which showed a lack of association between female sex and major bleeding events.[21,34]

Another novel finding from our analysis was that COPD is a strong predictor of bruising, respiratory, gastrointestinal, and genitourinary bleeding events. Most contemporary studies in the ACS setting have either not included COPD as a potential predictor or not recorded its diagnosis. Our finding on the effect of COPD on the occurrence of bleeding suggests that COPD should be taken into account when evaluating future risk of bleeding complications. COPD is characterized by local and systemic inflammation.[35] Patients with COPD are exposed to oxidative stress via chronic hypoxia and increased release of reactive oxygen species by leukocytes.[36] This damages gastric mucosa[37] and may predispose to peptic ulcer bleeds.[38] Patients with COPD are often treated with steroids to control lung inflammation. Steroids may delay peptic ulcer healing,[39] thus increasing the risk of perforation and bleeding complications.[40] The association of COPD with bleeding events should be explored further to confirm the result of our study.

Our study found cancer to be a strong predictor of respiratory bleeding events and a modest nonsignificant increased risk of gastrointestinal bleeds. Malignancy has been an exclusion criterion in previous studies, such as the CRUSADE (Can rapid risk stratification of unstable angina patients suppress adverse outcomes with early

Data are given as sub–hazard ratio (95% CI). ACS indicates acute coronary syndrome; BMI, body mass index; CKD, chronic kidney disease; COPD, chronic obstructive pulmonary disease; eGFR, estimated glomerular filtration rate; ENT, ears, nose, and throat; NSTEMI, non ST-segment–elevation myocardial infarction; PCI, percutaneous coronary intervention; PVD, peripheral vascular disease; SSRI, selective serotonin reuptake inhibitor; STEMI, ST-segment–elevation myocardial infarction.

*Adjusted for year of hospital discharge, geographic region, general practice, and all listed characteristics in the table.

†Statistically significant predictors of bleeding at the 5% threshold.

‡Included as time-dependent coefficient: estimated sub–hazard ratio at day of hospital discharge but decreases with time after discharge (1.00=reference category).

§Included as time-dependent coefficient: estimated sub–hazard ratio at day of hospital discharge but increases with time after discharge.

implementation of the ACC/AHA guidelines), DAPT (Dual antiplatelet therapy study), and Trilogy-ACS (Targeted platelet inhibition to clarify the optimal strategy to medically manage acute coronary syndromes).[8,12,13] Cancers that are systemic, such as those emanating from the gastroesophageal tract, are more likely to increase bleeding complications. Therefore, thoughtful consideration should be given to this group of patients when deciding on secondary management strategy after ACS. We found dual antiplatelet therapy to be associated with a decreased risk of gastrointestinal bleed in the immediate period after hospital discharge. The decreased risk of gastrointestinal bleed with dual antiplatelet may be caused by an element of confounding by indication, with patients deemed to be at highest risk for this type of bleed only prescribed single antiplatelet at the time of hospital discharge.

We found treatment with oral anticoagulants to be associated with higher risk of respiratory, genitourinary, and intraocular bleeding events after hospital discharge. Of patients in our study, 6% were prescribed oral anticoagulants, with most (92%) given warfarin at discharge. Replacing warfarin with the newer oral anticoagulants that have a more favorable safety profile may mitigate the bleeding complications in this group of patients.[41,42] In patients managed with PCI, who have an indication for oral anticoagulants, such as those with atrial fibrillation who are at increased risk of stroke, secondary management involving an antiplatelet (eg, clopidogrel) and a newer oral anticoagulant, as stipulated in the updated American Heart Association guideline for the management of patients with atrial fibrillation, will reduce the risk of late bleeding events.[43] For patients prescribed triple therapy (aspirin plus P2Y12 inhibitor plus an oral anticoagulant), the duration of this therapy should be minimized to a period of 4 to 6 weeks and dual therapy (a P2Y12 inhibitor plus an oral anticoagulant) should be considered thereafter,[43] to minimize the risk of bleeding.

The findings of this study should be interpreted in light of some limitations. First, bleeding events were not independently adjudicated. The observational design of the study does not preclude residual confounding. The definition for bleeding did not include laboratory parameters, such as decrease in hemoglobin measurements and/or receipt of blood transfusion. Classifying bleeding on the basis of severity (major and minor) was, therefore, not possible. The study was not adequately powered to examine the independent predictors of some types of bleeding events, such as intracranial and intraocular bleeds that occurred relatively rarely. Thus, findings in relation to these bleeding events should be viewed as exploratory. Reporting bias may be a cause for concern in our study because not all patients who experience minor and nuisance bleeding events (eg, nose bleeds and bruising) will seek medical advice. Therefore, the incidence of bleeding is likely to have been underreported, although more significant bleeds may have been likely recorded. Prasugrel, ticagrelor, and the newer oral anticoagulants became available during the study period, but most patients (90%) were mostly treated with aspirin, clopidogrel, or warfarin after discharge. We restricted our study to people in England. Thus, the generalizability of our results outside of England is unclear. Finally, we were unable to examine the impact of dosing and duration of discharge antithrombotic drugs and those of emerging risk factors, such as frailty and genetic factors, on risk of future bleeding events.

In summary, bleeding complications after hospital discharge are common and occur more frequently in the first 30 days after hospital discharge. Patients who experience these bleeding events have distinct baseline characteristics. These characteristics differ, depending on the anatomic site of the bleeding event. Identification of these characteristics is an important step toward developing a real-world risk stratification tool that can facilitate a more patient-centered approach in deciding on favorable combination and duration of secondary antithrombotic therapy after ACS.

Supplemental Material

Data S1.

Clinical Practice Research Datalink (CPRD)

The CPRD is a primary care database containing individual patient's demographic information, tests, clinical events (such as diagnosis), referrals, prescriptions, and immunisations from a subset of UK general practices that had consented to periodically provide patient data for research purposes (1). In the UK, general practices are the first point of contact for non-emergency health related issues, and diagnoses during these encounters are electronically recorded using the Read coding system. A subset of practices in England (75% of English practices, 55% of all UK practices) contributing to CPRD have consented to their primary care records being linked to HES and ONS (1). CPRD is generally representative of the UK population on age, gender and ethnicity (1, 2).

Table S1. Candidate predictors of bleeding for model development.

Socio-demographic characteristics (recorded in the 2 years prior to index date except BMI which was recorded until 30 days after index date)
Advanced age
Female sex
Body mass index* (BMI)
History of smoking†
Comorbidities (recorded in the 2 years prior to index date)
History of diabetes
History of hypertension
History of heart failure
History of cancer
History of peripheral vascular disease
History of chronic obstructive pulmonary disease (COPD)
History of renal insufficiency‡
Hyperlipidemia
History of bleeding
STEMI at presentation
NSTEMI at presentation
In-hospital procedure
Percutaneous coronary intervention (PCI) at index ACS hospitalisation
Pharmacological characteristics
NSAID prescription within 6 months prior to hospital discharge
SSRI prescription within 6 months prior to hospital discharge
Discharge antithrombotic therapy§ (whether single antiplatelet (SAPT), dual antiplatelet (DAPT) or receipt of oral anticoagulant)

[*]BMI was classified into underweight, normal weight, overweight, and obese following the WHO classification.

[†]Smoking was defined as non-smoker, ex-smoker and current smoker.

[‡]Renal insufficiency was defined by Estimated Glomerular Filtration Rate (eGFR), calculated using the Chronic Kidney Disease Epidemiology Collaboration Equation (CKD-EPI) as eGFR < 60 mL/min per 1.73 m^2 (3).

[§]Discharge antithrombotic therapy was classified into **single antiplatelet therapy** (a prescription record for one of aspirin, clopidogrel, prasugrel or ticagrelor), **dual antiplatelet therapy** (a prescription record for aspirin and one of clopidogrel, prasugrel or ticagrelor) and **receipt of oral anticoagulation** (a prescription record for one of warfarin, apixaban, rivaroxaban or dabigatran, with or without concomitant antiplatelets) all measured within 90 days post index date in the patient's primary care record.

Table S2. Baseline characteristics of the study population by site of bleeding events within the first 12 months after hospital discharge.

Demographic characteristics	No Bleeds (n = 24040)	Bruising (n = 949)	Respiratory/ent bleeds (n = 582)	Gastrointestinal bleeds (n = 705)	Genitourinary bleeds (n = 468)	Intraocular bleeds (n = 135)	Intracranial bleeds (n = 81)
Age (Mean ± SD)	69.6 ± 13.7	69.6 ± 13.0	72.6 ± 12.7	71.9 ± 13.6	72.1 ± 13.5	72.4 ± 10.9	76.3 ± 11.8
Age (n, %)
